

Clone 84 feature preservation, by integration

7 integrations x 272 sites, 250 cells; simulations masked with the real missingness pattern

A

Every feature, integration by integration

Integrations are matched by position (i-th sorted barcode against int_i), not by identity

B

Level and spread across integrations

Point is the mean over integrations, whiskers are one standard deviation, in each metric's own units; axes start at zero

Integrations correspond by position, not identity, so these are distributions over integrations rather than 7 paired comparisons. The lower row shows level and spread together -- mean over integrations with one-SD whiskers -- because spread alone reads as though it contradicts the panel above: real barcodes have the lowest homoplasmy AND vary the most. SD is used rather than coefficient of variation, since the datasets differ twofold in mean on several metrics and dividing by the mean would report that level difference a second time. Axes start at zero so the proportional comparisons read correctly. Normalised entropy is the one exception: it is bounded at 1 and every dataset sits above 0.95, so a zero baseline would hide a real difference. Read that panel, and only that panel, as a zoom.
