

Does the FLARE recorder reproduce the HL60 Cas9 recording?

13,500,552 real molecules against 164,375 simulated, 8 targets each; depth fixed at 36 divisions and the rate scaled 5.3x to match saturation

Depth could not be the calibrated knob: at the grid's rate the simulator needs 109 divisions to reach the observed saturation, which is 7e10 cells. The rate had to be raised 6x the parameter grid's selected tier instead, which is itself a finding about that tier. Panel A is the calibrated quantity. Panels B to E were not calibrated and are where the model is tested: the simulation cannot produce an untouched array, collapses every deletion to one indistinguishable state, and leaves the eight targets near-independent where the real array edits as one unit.
