

Reproducing the clone 84 BASELINE recording in simulation

10 integrations x 272 sites, 250 cells, 30 cell divisions; per-target rates drawn from Gamma(shape, mean/shape)

A

Per-site editing rate

The real construct is U-shaped: most sites barely edit, a fifth saturate

B

Cumulative distribution

Vertical gaps are the mismatch; the shipped curve rises too early and saturates too late

C

Quantile agreement with the real data

Dashed line is exact agreement; points are the 1st to 99th percentiles

D

Edit burden per cell

Fraction of a cell's sites carrying an edit; the fitted shape is close, the shipped one undershoots

Mean editing rate is matched by construction in both simulated configurations, so agreement there is not evidence of anything. The test is the distribution. With the shipped dispersion constant (shape = 0.5) the simulator puts too much mass in the middle and almost none at saturation, missing the early-editing sites that resolve deep splits. Fitting the shape recovers the observed distribution closely. Edit burden per cell separates them far less than the distribution does (24% fitted, 31% real, 22% shipped), so burden alone is a weak test.
