

Does calibrating the editing-rate model change the reconstructed tree?

5 simulations, 10 resamples each of 250 cells and 5 BASELINE recorders; the rate models share a ground-truth tree within a seed

Seed is the unit of replication. Within one seed the replicates resample a single simulation, so a paired test there measures resampling noise rather than the effect: seeds 1 and 2 each gave a significant clone-assignment result, in opposite directions. Panel B therefore plots every seed rather than pooling. Topology accuracy and clade recall are the only differences that hold their sign across seeds, and they are the same measurement twice. Clone assignment and distance geometry are unresolved at this sample size, and clone ARI at k=5 is not interpretable at all: the perfect recorder reaches only 0.34 to 0.61 there, so the cut, not the recorder, is what the number describes.
